DATA MINING 2 Time Series - Similarity, Distances, Transformations and Clustering

Riccardo Guidotti

a.a. 2019/2020

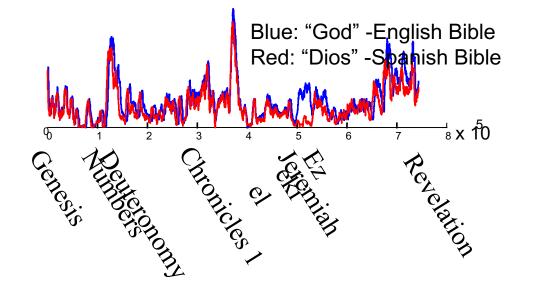

Slides edited from Keogh Eamonn's tutorial

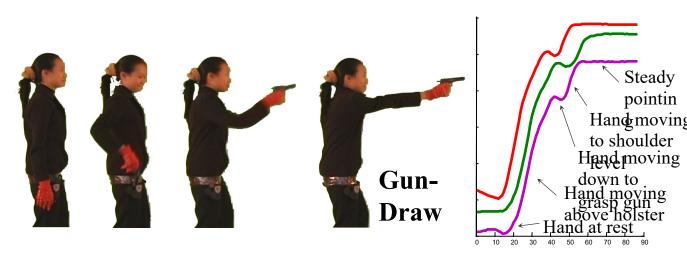

Time Series are Ubiquitous

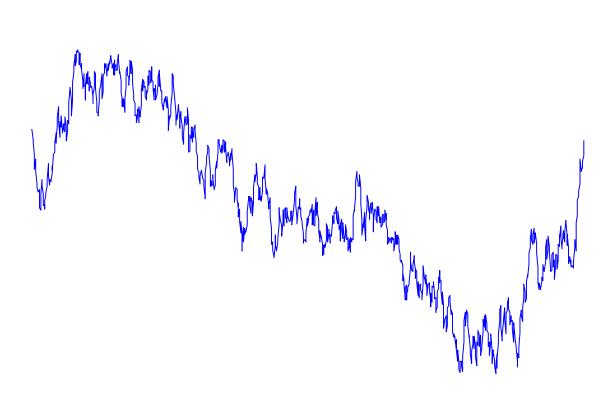

- You can measure many things ... and things change over time.
 - Blood pressure
 - Donald Trump's popularity rating
 - The annual rainfall in Pisa
 - The value of your stocks
- In addition other data type can thought of as time series
 - Text data: words count
 - Images: edges displacement
 - Videos: object positioning

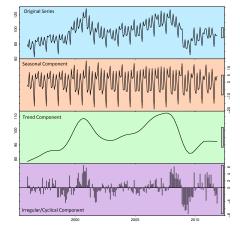

Problems in Working with Time Series

- Large amount of data.
- Similarity is not easy to estimate.
- Differing data formats.
- Differing sampling rates.
- Noise, missing values, etc.

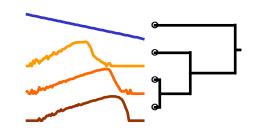

What We Can Do With Time Series?

• Trends, Seasonality

• Clustering

• Motif Discovery s = 0.5• Rule Discovery c = 0.3 Forecasting Classification

Ischemia

Similarity, Distances and Transformations

Similarity

- All these problems require similarity matching.
- What is Similarity?
 - It is the quality or state of being similar, likeness, resemblance, as a similarity of features.
- In time series analysis we recognize two kinds of similarity:
 - Similarity at the level of shape
 - Similarity at the structural level

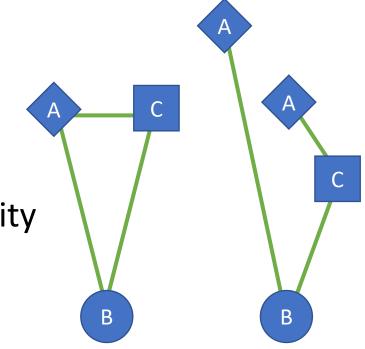

Shape-based Similarities

Defining Distance Measures

• Let A and B be two objects from the universe of possible objects. The distance (dissimilarity) is denoted by D(A,B).

Constancy

- Properties in a distance measure.
 - D(A,B) = D(B,A) Symmetry
 - D(A,A) = 0
 - D(A,B) = 0 IIf A = B Positivity
 - $D(A,B) \le D(A,C) + D(B,C)$ Triangular Inequality

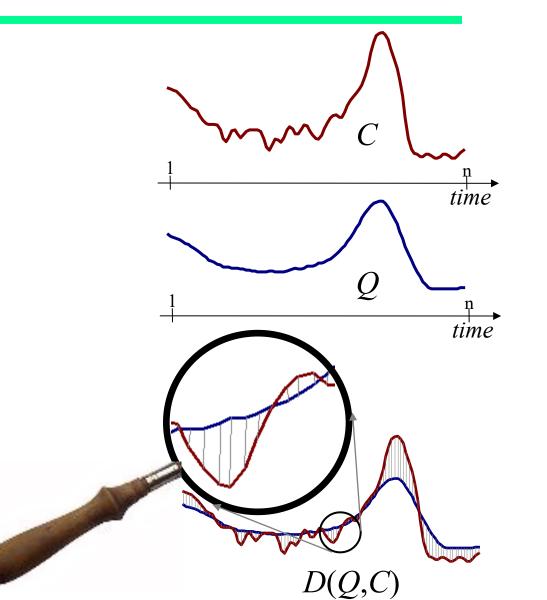

Euclidean Distance

- Given two time series:
 - $Q = q_1 \dots q_n$
 - $C = c_1 \dots c_n$

$$D(Q,C) \equiv \sqrt{\sum_{i=1}^{n} (q_i - c_i)^2}$$

• T1 = < 56, 176, 110, 95 > • T2 = < 36, 126, 180, 80 >

 $D(T1,T2) = sqrt [(56-36)^2 + (176-126)^2 + (110-180)^2 + (95-80)^2]$

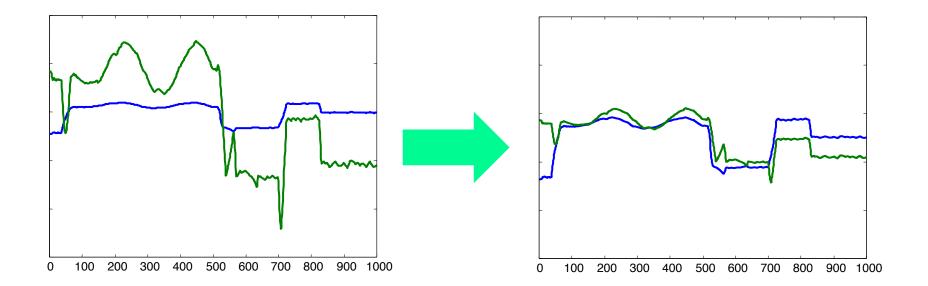

Problems with Euclidean Distance

- Euclidean distance is very sensitive to "distortions" in the data.
- These distortions are dangerous and should be removed.
- Most common distortions:
 - Offset Translation
 - Amplitude Scaling
 - Linear Trend
 - Noise
- They can be removed by using the appropriate transformations.

Transformation I: Offset Translation

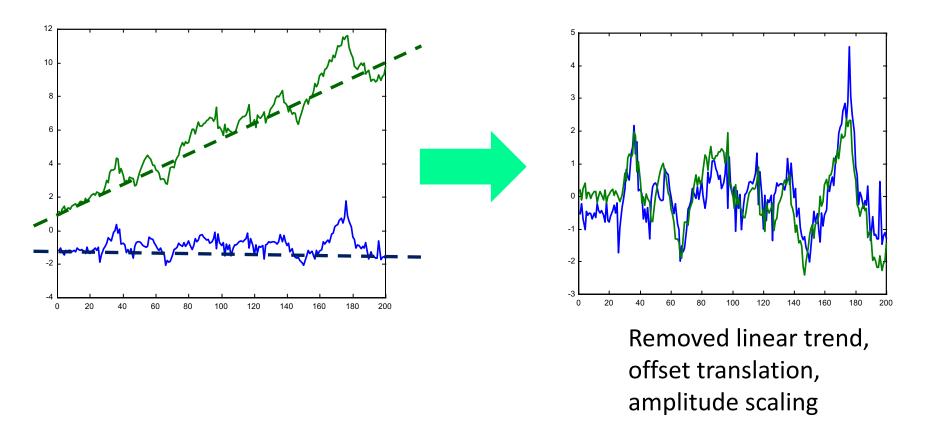

Transformation II: Amplitude Scaling

Q = (Q - mean(Q)) / std(Q) C = (C - mean(C)) / std(C) D(Q,C)

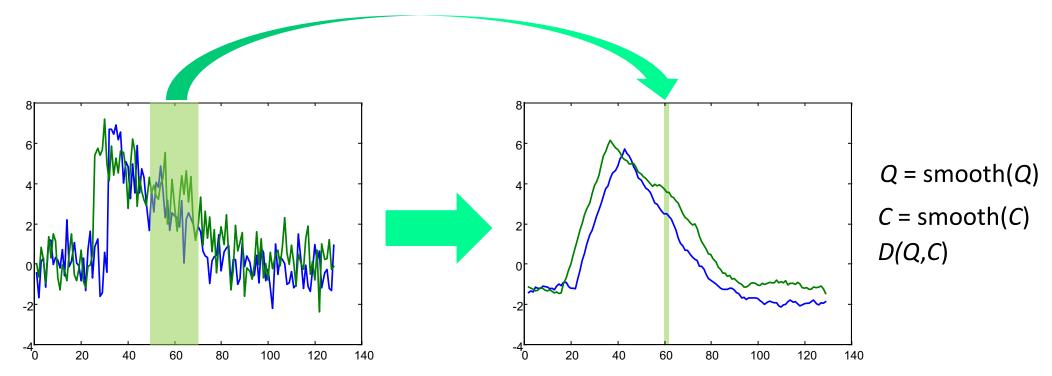

Transformation III: Linear Trend

• Removing linear trend: fit the best fitting straight line to the time series, then subtract that line from the time series.

Transformation IV: Noise

• The intuition behind removing noise is to average each datapoints value with its neighbors.

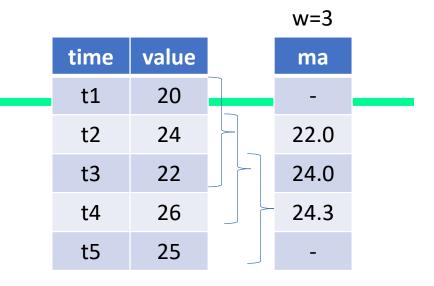

Moving Average

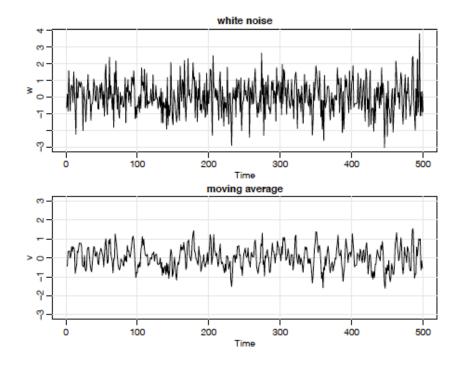

- Noise can be removed by a **moving average** (MA) that smooths the TS.
- Given a window of length *w* and a TS *t*, the MA is applied as follows

•
$$t_i = \frac{1}{w} \sum_{j=i-w/2}^{w/2} t_j$$
 for $i = 1, ..., n$

• For example, if w=3 we have

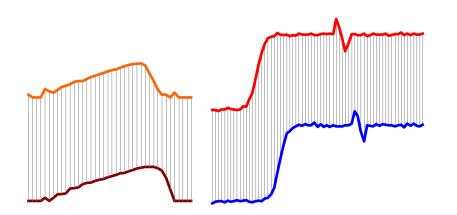

•
$$t_i = \frac{1}{3} (t_{i-1} + t_i + t_{i+1})$$

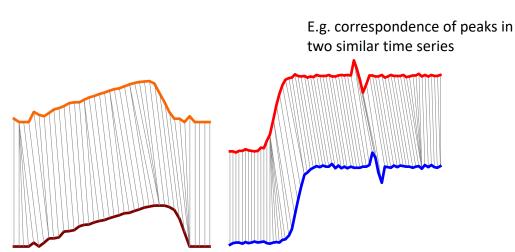

Dynamic Time Warping

 Sometimes two time series that are conceptually equivalent evolve at different speeds, at least in some moments.

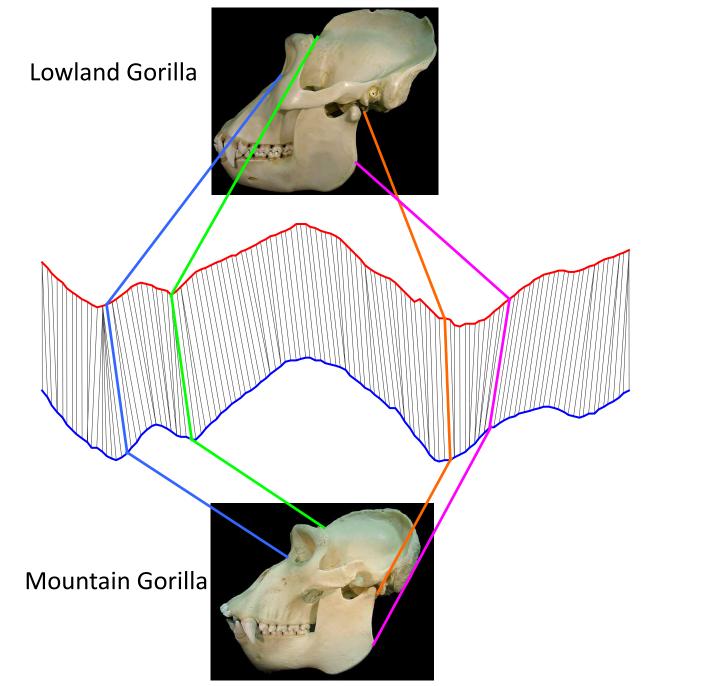

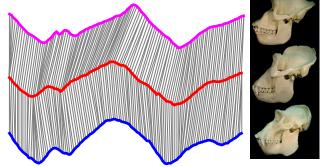

Fixed Time Axis. Sequences are aligned "one to one". Greatly suffers from the misalignment in data. Euclidean.

Warped Time Axis. Nonlinear alignments are possible. Can correct misalignments in data. Dynamic Time Warping.

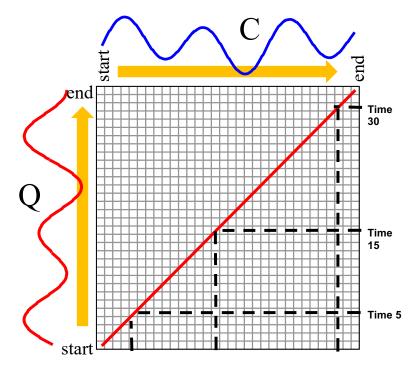

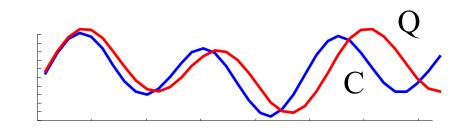

https://izbicki.me/blog/converting-images-into-time-series-for-data-mining.html

• We create a matrix the size of |Q| by |C|, then fill it in with the distance between every pair of point in our two time series.

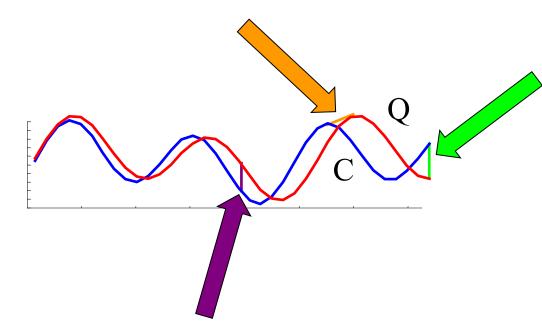

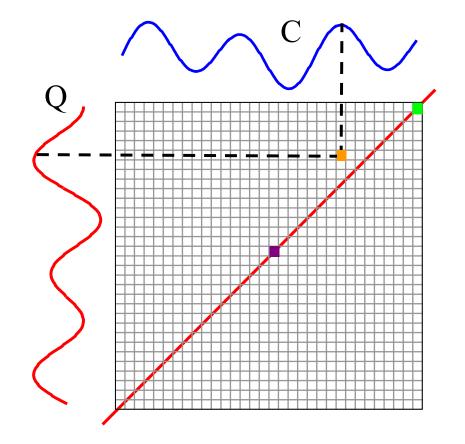

The Euclidean distance works only on the diagonal of the matrix. The sequence of comparisons performed:

- Start from pair of points (0,0)
- After point (*i*,*i*) move to (*i*+1,*i*+1)
- End the process on (n,n)

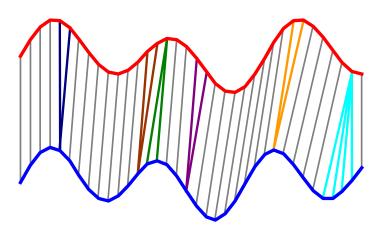

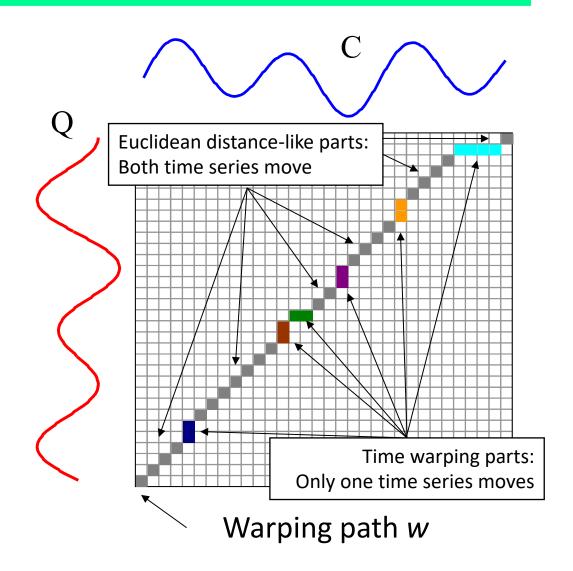

- The DTW distance can "freely" move outside the diagonal of the matrix
- Such cells correspond to temporally shifted points in the two time series

- Every possible warping between two time series, is a path through the matrix.
- The constrained sequence of comparisons performed:
 - Start from pair of points (0,0)
 - After point (*i*,*j*), either *i* or *j* increase by one, or both of them
 - End the process on (n,n)

- Every possible warping between two time series, is a path through the matrix.
- We find the best one using a recursive definition of the DTW:

 $\begin{aligned} \gamma(i,j) &= \text{cost of best path reaching cell } (i,j) \\ &= d(q_i,c_j) + \min\{ \gamma(i-1,j-1), \gamma(i-1,j), \gamma(i,j-1) \} \end{aligned}$

 Idea: best path must pass through (i-1,j), (i-1,j-1) or (i,j-1)

$$DTW(Q,C) = \min\left\{\sqrt{\sum_{k=1}^{K} w_k} \middle| K\right\}$$

 $w_k = \text{cost of the } k\text{-th points comparison}$

•
$$\mathbf{w}_k = |\mathbf{Q}_i - \mathbf{C}_j|$$

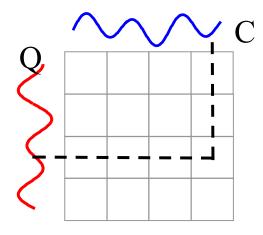

•
$$w_k = (Q_i - C_j)^2$$

Dynamic Programming Approach

Step 1: compute the matrix of all $d(q_i, c_j)$

• Point-to-point distances $D(i,j) = |Q_i - C_j|$

 $\gamma(i,j) = d(q_i,c_j) + \min\{\gamma(i-1,j-1), \gamma(i-1,j), \gamma(i,j-1)\}$ Step 2: compute the matrix of all path costs $\gamma(i,j)$

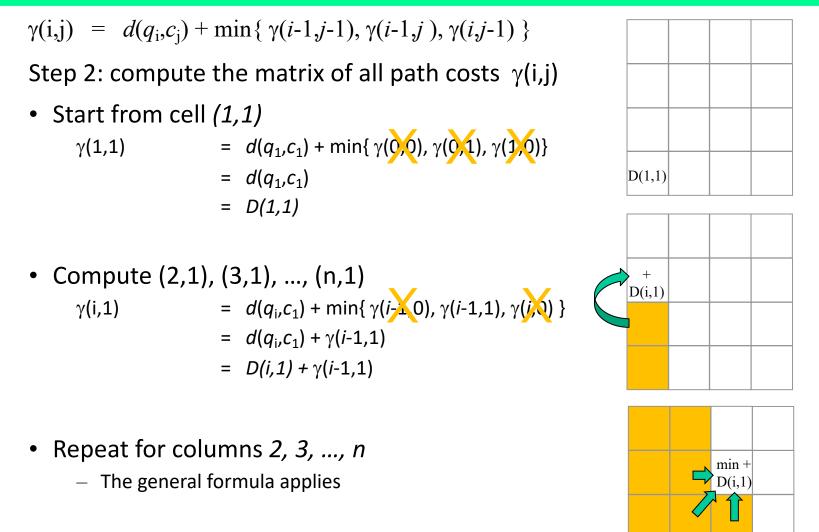

Step 3: find the path with the lowest value (best alignment)

- Start from cell (1,1)
- Compute (2,1), (3,1), ..., (n,1)
- Repeat for columns 2, 3, ..., n
- Final result in last cell computed

Dynamic Programming Approach

Dynamic Programming Approach

Example

• c = < 3, 7, 4, 3, 4 >

$$\gamma(\mathbf{i},\mathbf{j}) = d(q_{\mathbf{i}},c_{\mathbf{j}}) + \min\{\gamma(\mathbf{i}-1,\mathbf{j}-1),\gamma(\mathbf{i}-1,\mathbf{j}),\gamma(\mathbf{i},\mathbf{j}-1)\}$$

• q = < 5, 7, 6, 4, 2 >

Dynamic Time Warping – A Real Example

- A Real Example
- This example shows 2 oneweek periods from the power demand time series.
- Note that although they both describe 4-day work weeks, the blue sequence had Monday as a holiday, and the red sequence had Wednesday as a holiday.

Comparison of Euclidean Distance and DTW

Word Spotting

Comparison of Euclidean Distance and DTW

- Classification using 1-NN
- Class(x) = class of most similar training object
- Leaving-one-out evaluation
- For each object: use it as test set, return overall average

Dataset	Euclidean	DTW
Word Spotting	4.78	1.10
Sign language	28.70	25.93
GUN	5.50	1.00
Nuclear Trace	11.00	0.00

Milliseconds

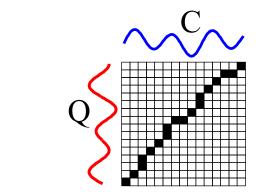

What we have seen so far...

- Dynamic Time Warping gives much better results than Euclidean distance on many problems.
- Dynamic Time Warping is very very slow to calculate!
- Is there anything we can do to speed up similarity search under DTW?

Fast Approximations to DTW

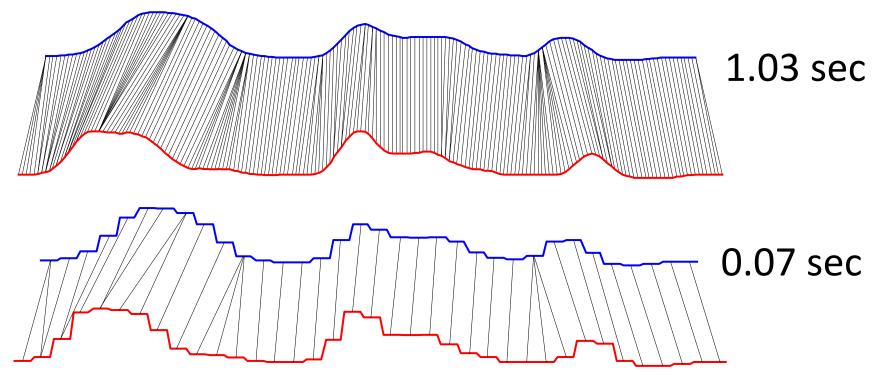

• Approximate the time series with some compressed or downsampled representation, and do DTW on the new representation.

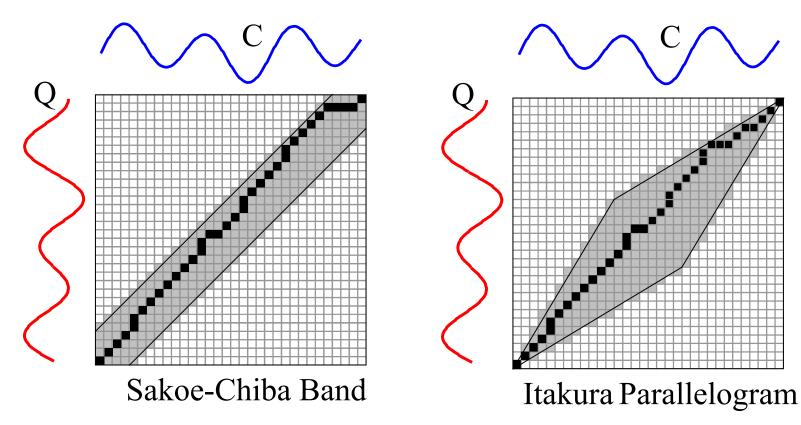

Fast Approximations to DTW

- There is strong visual evidence to suggests it works well
- In the literature there is good experimental evidence for the utility of the approach on clustering, classification, etc.

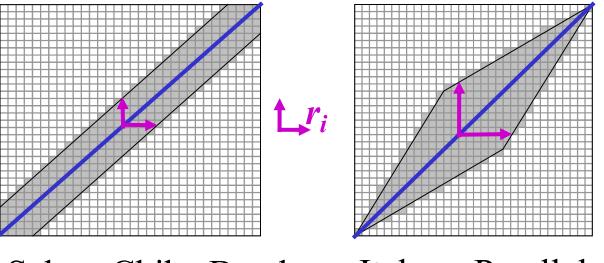

Global Constraints

- Slightly speed up the calculations
- Prevent pathological warpings

Global Constraints

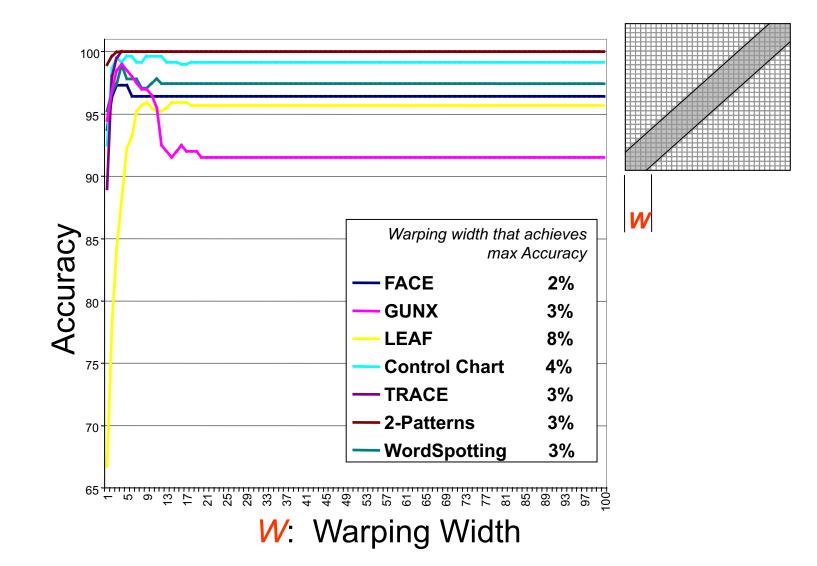

- A global constraint constrains the indices of the warping path $w_k = (i,j)_k$ such that $j-r \le i \le j+r$, where r is a term defining allowed range of warping for a given point in a sequence.
- r can be considered as a *window* that reduces the number of calculus.

Sakoe-Chiba Band

Itakura Parallelogram

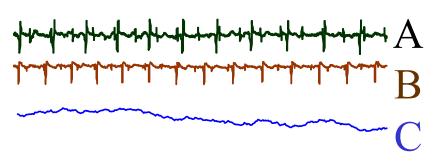

Accuracy vs. Width of Warping Window

Structural-based Similarities

Structure or Model Based Similarity

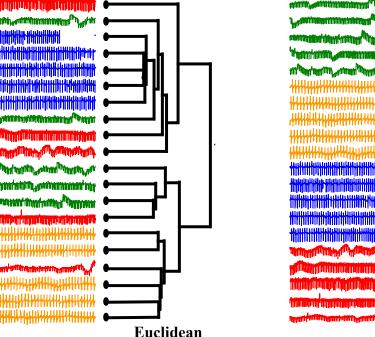

- For long time series, shape based similarity give very poor results.
- We need to measure similarly based on high level structure.
- The basic idea is to:
 - 1. extract global features from the time series,
 - 2. create a feature vector, and
 - 3. use it to measure similarity and/or classify
- Example of features:
 - mean, variance, skewness, kurtosis,
 - 1st derivative mean, 1st derivative variance, ...
 - parameters of regression, forecasting, Markov model

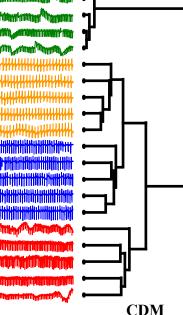

Feature\Time Series	Α	В	C
Max Value	11	12	19
Mean	5.3	6.4	4.8
Min Value	3	2	5
Autocorrelation	0.2	0.3	0.5
•••			

Compression Based Dissimilarity

- Use as features whatever structure a given compression algorithm finds.
- $d(x,y) = CDM(x,y) = \frac{C(x,y)}{C(x)+C(y)}$
- Time series can be compressed using various transformations:
 - Discrete Fourier Transformation
 - Piecewise Linear Approximation
 - Haar Wavelet
 - Adaptive Piecewise Constant Approximation
 - Symbolic Aggregate Approximation

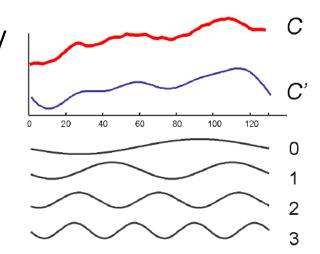

Time Series Approximation

Discrete Fourier Transform (DFT)

- Represent the time series as a linear combination of sines and cosines, but keep only the first n/2 coefficients.
- Why n/2 coefficients? Because each sine wave requires 2 numbers, for the phase (w) and amplitude (A,B).
- A TS represented with DTF is said to be in the frequency domain.
- Many of the Fourier coefficients have very low amplitude and thus contribute little to reconstructed signal. These low amplitude coefficients can be discarded without much loss of information thereby saving storage space.
- Pros
 - Good ability to compress most natural signals.
 - Fast, off the shelf DFT algorithms exist. O(nlog(n)).
- Cons
 - Difficult to deal with sequences of different lengths.
 - Cannot support weighted distance measures.

Jean Fourier 1768-1830

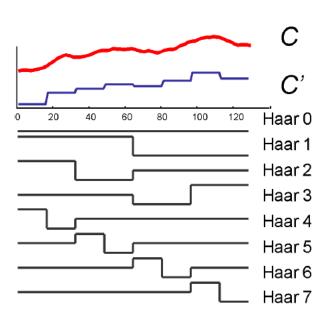

Discrete Wavelet Transform (DWT)

- Represent the TS as a linear combination of Wavelet basis functions, but keep only the first N coefficients.
- Wavelets are represent data in terms of the sum and difference of a prototype function, so called the "analyzing" or "mother" wavelet.
- Wavelets are localized in time, i.e., some of the *wavelet* coefficients represent small, *local* subsections of the data. This is in contrast to *Fourier* coefficients that always represent *global* contribution to the data.
- Haar wavelets seem to be as powerful as the other wavelets for most problems and are very easy to code.
- Pros
 - Good ability to compress stationary signals.
 - Fast linear time algorithms for DWT exist.
- Cons
 - It is only defined for sequence whose length is an integral power of two.
 - Otherwise wavelets approximate the left side of signal at the expense of the right side.
 - Cannot support weighted distance measures.

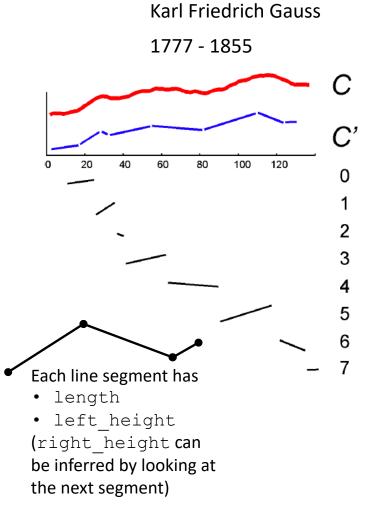

Alfred Haar 1885-1933

Piecewise Linear Approximation (PLA)

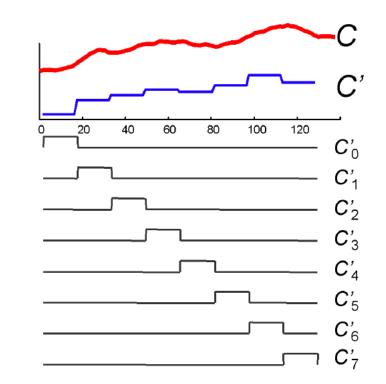

- Represent the time series as a sequence of straight lines.
- Lines could be connected, in which case we are allowed K/2 lines, If lines are disconnected, we are allowed only K/3 lines
- In the literature there are numerous algorithms available for **segmenting** time series.
- An open question is how to best choose K, the "optimal" number of segments used to represent a particular time series.
- This problem involves a tradeoff between accuracy and compactness, and clearly has no general solution.
- Pros:
 - data compression
 - noise filtering
 - able to support some interesting non-Euclidean similarity measures

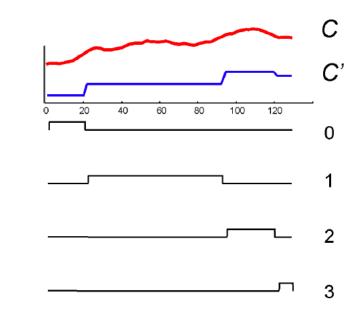

Piecewise Aggregate Approximation (PAA)

- Represent the time series as a sequence of box basis functions with each box of the same size.
- It approximates a TS by dividing it into equallength segments and recording the mean value of the data points that fall within the segment.
- It reduces the data from n dimensions to N dimensions by dividing the time series into N equisized ``frames''.
- The mean value of the data falling within a frame is calculated, and a vector of these values becomes the data reduced representation.
- Pros
 - Extremely fast to calculate
 - Supports non Euclidean measures
 - Supports weighted Euclidean distance

Adaptive Piecewise Constant Approximation (APCA)

- It allows the segments to have arbitrary lengths, which in turn needs two numbers per segment.
- The first number records the mean value of all the data points in segment, and the second number records the length of the segment.
- APCA has the advantage of being able to place a single segment in an area of low activity and many segments in areas of high activity.
- In addition, one has to consider the structure of the data in question.
- Pros:
 - Fast to calculate O(n)
 - Supports non Euclidean measures
 - Supports weighted Euclidean distance

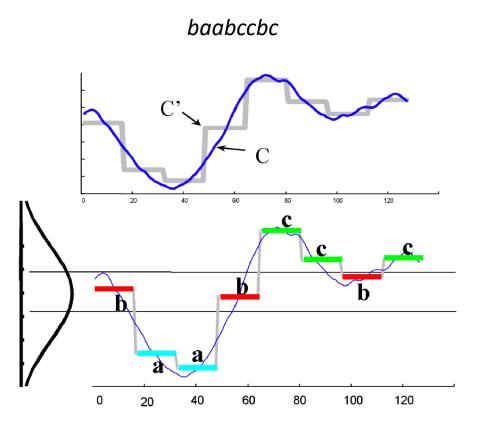

Symbolic Aggregate Approximation (SAX)

- Convert the data into a discrete format, with a *small alphabet size*.
- Every part of the representation contributes about the same amount of information about the shape of the time series.
- A time series **T** of length **n** is divided into **w** equal-sized segments; the values in each segment are then approximated and replaced by a single coefficient, which is their average. Aggregating these w coefficients form the PAA representation of **T**.
- Next, we determine the breakpoints that divide the distribution space into a equiprobable regions, where a is the alphabet size specified by the user (or it could be used the MDL).
- The breakpoints are determined such that the probability of a segment falling into any of the regions is approximately the same.
- If the symbols are not equi-probable, some of the substrings would be more probable than others. Consequently, we would inject a probabilistic bias in the process.

Symbolic Aggregate Approximation (SAX)

- Once the breakpoints are determined, each region is assigned a symbol.
- The PAA coefficients can then be easily mapped to the symbols corresponding to the regions in which they reside.
- The symbols are assigned in a bottom-up fashion, i.e., the PAA coefficient that falls in the lowest region is converted to "a", in the one above to "b", and so forth.

Summary of Time Series Similarity

- If you have short time series
 - use DTW after searching over the warping window size
- If you have long time series
 - if you do know something about your data => extract features
 - and you know nothing about your data => try compression/approximation based dissimilarity

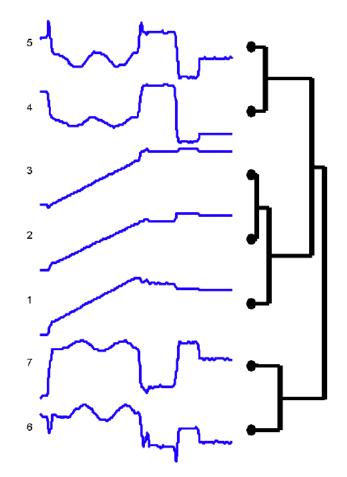

Clustering

Clustering Time Series

- It is based on the similarity between time series.
- The most similar data are grouped into clusters, but the clusters themselves should be dissimilar.
- These groups to find are not predefined, i.e., it is an unsupervised learning task.
- The two general methods of time series clustering are
 - Partitional Clustering and
 - Hierarchical Clustering

Hierarchical Clustering

- It *computes pairwise distance*, and then merges similar clusters in a bottom-up fashion, without the need of providing the number of clusters
- It is one of the best tools to data evaluation, by creating a dendrogram of several time series from the domain of interest.
- Its application is limited to small datasets due to its quadratic computational complexity.

Partitional Clustering

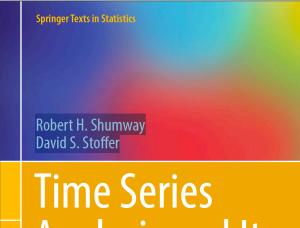

- Typically uses the K-Means algorithm (or some variant) to optimize the objective function by minimizing the sum of squared intra-cluster errors.
- K-Means is perhaps the most commonly used clustering algorithm in the literature, one of its shortcomings is the fact that the number of clusters, K, must be pre-specified.
- Also the *distance function plays a fundamental role* both for the quality of the results and for the efficiency.

Types of Time Series Clustering

- Whole clustering: similar to that of conventional clustering of discrete objects. Given a set of individual time series data, the objective is to group similar time series into the same cluster.
- *Features-based clustering*: extract features, or time series motifs (see next lectures) as the features and use them to cluster time series.
- **Compression-based clustering**: compress time series and run clustering on the compressed versions.
- **Subsequence clustering**: given a single time series, subsequence clustering is performed on each individual time series extracted from the long time series with a sliding window.
