DATA MINING 2 Transactional Clustering

Riccardo Guidotti

a.a. 2020/2021

Clustering

• **Clustering**: Grouping of objects into different sets, or more precisely, the partitioning of a data set into subsets (clusters), so that the data in each subset (ideally) share some common trait - often proximity according to some defined distance measure

- Common distance functions:
 - Euclidean distance, Manhattan distance, ...

This kind of distance functions are suitable for numerical data

Not Only Numerical Data

Acceleration 0-100 (s)	Lenght (m)	Width (m)	Height (m)	Price (€)
12	4	1.6	1.7	20' 000
14	3.7	1.5	1.65	16' 000
15	3.5	1.5	1.6	12'000
9,4	4.2	1.8	1.7	24' 000

Numerical Data

Categorical Data

Hairs	Eyes
brown	black
blond	blue
black	green
red	brown

Boolean and Categorical Attributes

• A **boolean** attribute corresponding to a single item in a transaction, if that item appears, the boolean attribute is set to '1' or '0' otherwise.

• A categorical attribute may have several values, each value can be treated as an item and represented by a boolean attribute.

Market Basket Data

- A transaction represents one customer, and each transaction contains set of items purchased by the customer.
- Clustering customers reveals customers with similar buying patterns putting them into the same cluster.
- It is useful for
 - Characterizing different customer groups
 - Targeted Marketing
 - Predict buying patterns of new customers based on profile
- A market basket database: A scenario where attributes of data points are non-numeric, transaction viewed as records with boolean attributes corresponding to a single item (TRUE if transaction contain item, FALSE otherwise).
- Boolean attributes are special case of Categorical attributes.

Shortcomings of Traditional Clustering

- For categorical data we:
 - Define new criterion for *neighbors* and/or *similarity*
 - Define the ordering criterion
- Consider the following 4 market basket transactions

 using Euclidean distance to measure the closeness between all pairs of points, we find that d(P1,P2) is the smallest distance: it is equal to 1

Shortcomings of Traditional Clustering

- If we use a hierarchical algorithm then we merge P1 and P2 and get a new cluster (P12) with (1, 1, 0.5, 1) as a centroid
- Then, using Euclidean distance again, we find:
 - $d(p12,p3) = \sqrt{3.25}$
 - $d(p12,p4) = \sqrt{2.25}$
 - $d(p3,p4) = \sqrt{2}$
- So, we should merge P3 and P4 since the distance between them is the shortest.
- However, T3 and T4 don't have even a single common item.
- So, using distance metrics as similarity measure for categorical data is not appropriate.

```
P1= (1, 1, 1, 1)
P2= (1, 1, 0, 1)
P3= (0, 0, 1, 0)
P4= (0, 0, 0, 1)
```

Clustering Algorithms for Categorical/Transactional Data

- K-Modes
- ROCK
- CLOPE
- TX-Means

K-Modes

Minimise
$$P(W, \mathbf{Q}) = \sum_{l=1}^{k} \sum_{i=1}^{n} w_{i,l} d(X_i, Q_l)$$

subject to $\sum_{l=1}^{k} w_{i,l} = 1, \quad 1 \le i \le n$
 $w_{i,l} \in \{0, 1\}, \quad 1 < i < n, \ 1 < l < k$

- $X = \{X_1, ..., X_n\}$ is the dataset of objects.
- $X_i = [x_1, ..., x_m]$ is an object i.e., a vector of m categorical attributes
- W is a matrix $n \times k$, with $w_{i,l}$ equal to 1 if X_i belongs to Cluster l, 0 otherwise.
- $Q = \{Q_1, ..., Q_k\}$ is the set of representative objects (mode) for the k clusters.
- $d(X_i, Q_i)$ is a distance function for objects in the data

K-Modes: Distance

 K-Means as distance uses Euclidean distance

$$d(X,Y) = \sum_{i=1}^{m} (x_i - y_i)^2$$

 K-Modes as distance uses the number of mismatches between the attributes of two objects.

$$d_1(X, Y) = \sum_{j=1}^m \delta(x_j, y_j)$$

$$\delta(x_j, y_j) = \begin{cases} 0 & (x_j = y_j) \\ 1 & (x_j \neq y_j) \end{cases}$$

K-Modes: Mode

- K-Modes uses the mode as representative object of a cluster
- Given the set of objects in the cluster C_l the mode is get computing the max frequency for each attribute

$$f_r(A_j = c_{l,j} | X_l) = \frac{n_{c_{l,k}}}{n}$$

K-Modes: Algorithm

- 1. Randomly select the initial objects as modes
- 2. Scan of the data to assign each object to the closer cluster identified by the mode
- 3. Re-compute the mode of each cluster
- 4. Repeat the steps 2 and 3 until no object changes the assigned cluster

ROCK: RObust Clustering using link

- ROCK is a hierarchical algorithm for clustering transactional data (market basket databases)
- ROCK uses links to cluster instead of the classical distance notion
- ROCK uses the notion of neighborhood between pair of objects to identify the number of links between two objects

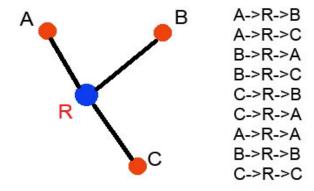

ROCK: The Neighbors Concept

- It captures a notion of similarity
 - A and B are neighbors if $sim(A, B) \ge \theta$
- ROCK uses the Jaccard coefficient
 - sim(A, B)= |A ∩ B| / | A U B |

$$sim(A,B) = \frac{3}{6} = \frac{1}{2} = 0.5$$

ROCK: Links

- A link defines the number of common neighbors between two objects:
- link(A, B) = | neighbor(A) ∩ neighbor(B) |
- Higher values of link(A, B) means higher probability that A and B belong to the same cluster
- Similarity is local while link is capturing global information
- A point is considered a neighbor of itself
- There is a link from each neighbor of the "root" point back to itself through the root
- Therefore, if a point has n neighbors, then n^2 links are due to it.

ROCK: Example

- Data consisting of 6 Attributes:
- {Book, Water, Sun, Sand, Swimming, Reading}

- {Book}
- {Water, Sun, Sand, Swimming}
- {Water, Sun, Sand, Reading}
- {Reading, Sand}
- Resulting Jaccard Coefficient Matrix
- Set Threshold = 0.2. Neighbors:
 - N(A)={A}; N(B)={B,C,D}
 - N(C)={B,C,D}, N(D) = {B,C,D}
- Number of Links Table
 - Link (B, C) = $|\{B,C,D\}| = 3$

	A	В	C	D
A	1	0	0	0
В	0	1	0.6	0.2
С	0	0.6	1	0.5
D	0	0.2	0.5	1

	Α	В	С	D
A	1	0	0	0
В	0	3	3	3
C	Ο	3	3	3
D	0	3	3	3

• Resulting Clusters after applying ROCK: {A}, {B,C,D}

ROCK – Criterion Function

Maximize

$$E_{l} = \sum_{i=1}^{k} n_{i} * \sum_{p_{q}, p_{r} \in C_{i}} \frac{link(p_{q}, p_{r})}{(n_{i}^{1+2f(\theta)})}$$

$$f(\theta) = \frac{1 - \theta}{1 + \theta}$$

Dividing by the number of expected links between pairs of objects in the cluster C_i we avoid that objects with a low number of links are assigned all to the same cluster

Where C_i denotes cluster i n_i is the number of points in C_i k is the number of clusters θ is the similarity threshold

This goodness measure helps to identify the best pair of clusters to be merged during each step of ROCK.

$$g(C_i,C_j) = \underbrace{\frac{link[C_i,C_j]}{(n_i+n_j)^{1+2f(\theta)}-n_i^{1+2f(\theta)}-n_j^{1+2f(\theta)}}}_{\text{Number of expected cross-links between two clusters}}$$

Input:

A set S of data points
Number of k clusters to be found
The similarity threshold

Output:

Groups of clustered data

The ROCK algorithm is divided into three major parts:

- 1. Draw a random sample from the data set
- 2. Perform a hierarchical agglomerative clustering algorithm
- 3. Label data

Draw a random sample from the data set:

- Sampling is used to ensure scalability to very large data sets
- The initial sample is used to form clusters, then the remaining data on dataset is assigned to these clusters

Perform a hierarchical agglomerative clustering algorithm:

- ROCK performs the following steps which are common to all hierarchical agglomerative clustering algorithms, but with different definition to the similarity measures:
 - 1. Places each single data point into a separate cluster
 - 2. Compute the similarity measure for all pairs of clusters
 - 3. Merge the two clusters with the highest similarity (goodness measure)
 - 4. Verify a stop condition. If it is not met then go to step 2.

Label data

- Finally, the remaining data points are assigned to the clusters.
- This is done by selecting a random sample L_i from each cluster C_i , then we assign each point p to the cluster for which it has the strongest linkage with L_i .

ROCK Summary

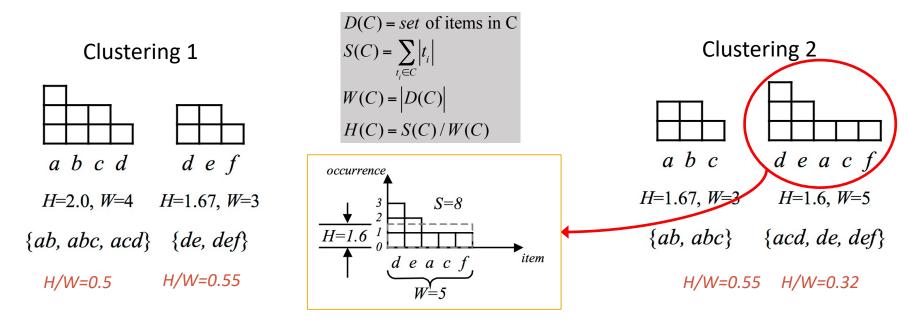

Input: dataset, number of clusters.

- 1. Draw a random sample from the data set
- 2. Places each data point into a separate cluster
- 3. Compute the similarity measure for all pairs of clusters
- 4. Merge the two clusters with the highest similarity
- 5. Verify a stop condition. If it is not met then go to step 2.
- 6. Assign not used points to clusters using linkage similarity with respect to selected samples from each cluster

CLOPE: Clustering with sLOPE

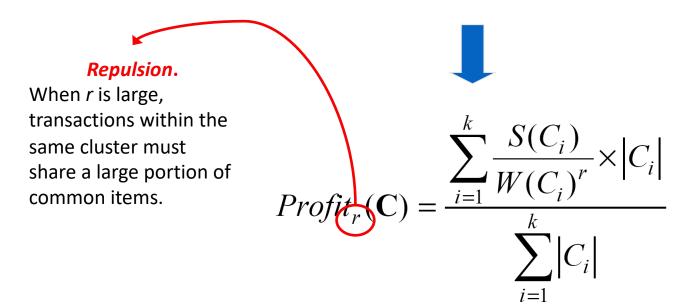

- Transactional clustering efficient for high dimensional data
- Uses a **global criterion function** that tries to increase the intra-cluster overlapping of transaction items **by increasing the height-to-width ratio of the cluster histogram**.

Example: 5 transactions {a,b} {a,b,c} {a,c,d} {d,e} {d,e,f}

CLOPE: Criterion Function

- For evaluating the goodness of a clustering the gradient of a cluster is
- G(C)=H(C)/W(C)=S(C)/W(C)²

CLOPE: Algorithm

```
/* Phrase 1 - Initialization */
1: while not end of the database file
      read the next transaction \langle t, \text{unknown} \rangle;
      put t in an existing cluster or a new cluster C_i
        that maximize profit;
      write \langle t, i \rangle back to database;
4:
   /* Phrase 2 - Iteration */
5: repeat
      rewind the database file;
     moved = false;
      while not end of the database file
9:
         read \langle t, i \rangle;
         move t to an existing cluster or new cluster C_i
10:
            that maximize profit;
         if C_i \neq C_j then
11:
            write \langle t, j \rangle;
12:
13:
            moved = true;
14: until not moved;
```

CLOPE Summary

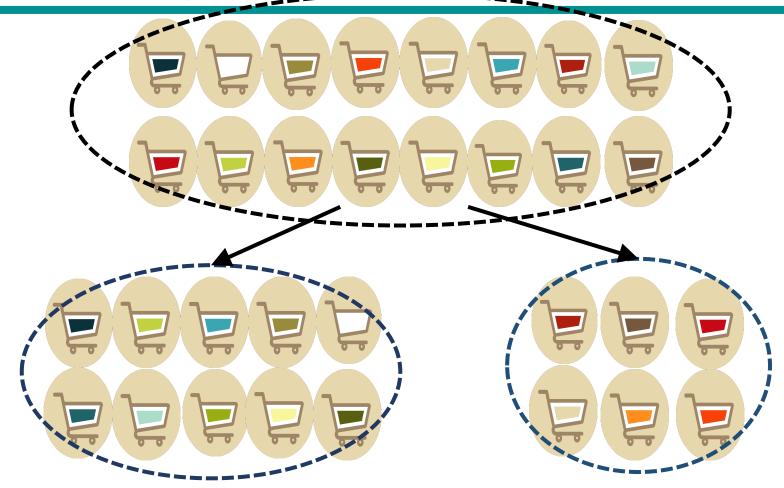

Input: dataset, repulsion, maximum number of clusters

- Phase 1
- 1. For each transaction, add it to a new cluster or to an existing one such that the profit is maximized
- Phase 2
- 1. For each transaction, try to move it to another cluster and do it if this maximizes the profit
- 2. Repeat 1. until all the transactions remain in the same cluster

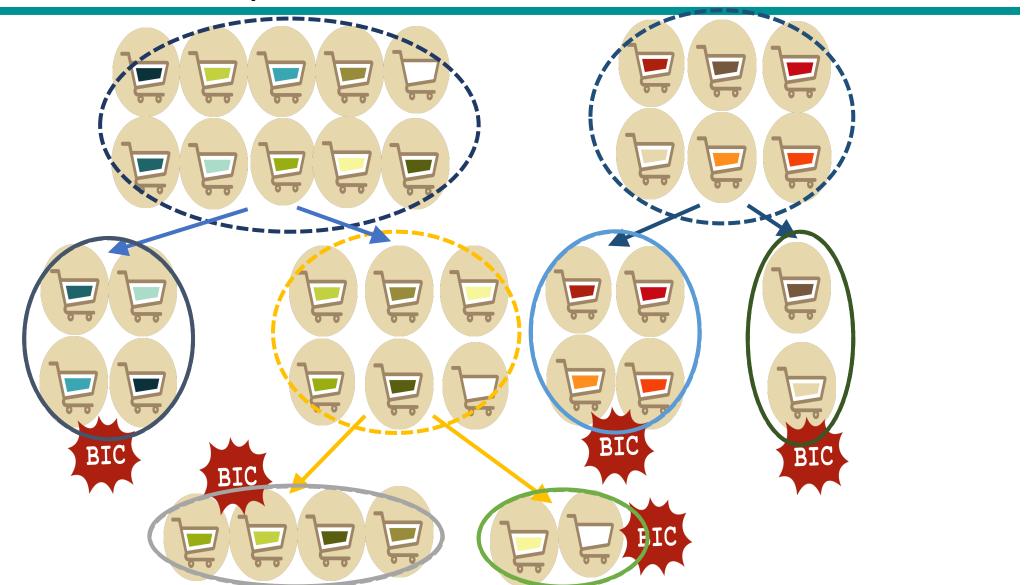

TX-MEANS

- A parameter-free clustering algorithm able to efficiently partitioning transactional data automatically
- Suitable for the case where clustering must be applied on a massive number of different datasets
 - E.g.: when a large set of users need to be analyzed individually and each of them has generated a long history of transactions
- TX-Means automatically estimates the number of clusters
- TX-Means provides the representative transaction of each cluster, which summarizes the pattern captured by that cluster.

• Return r;
```

Dealing with Big Datasets

- Clustering of a big individual transactional dataset B.
- TX-Means is scalable thanks to the following sampling strategy.

- Sampling strategy:
 - Random selection of a subset S of the baskets in B;
 - Run of TX-Means on the subset S and obtain clusters C and representative baskets R;
 - Assign the remaining baskets B/S to the clusters C using a nearest neighbor approach with respect to the representative baskets R.

X-means: Extending K-means with Efficient Estimation of the Number of Clusters

Dan Pelleg Andrew Moor

School of Computer Science, Carnegie Mellon University, Pittsburgh, PA 15213 USA

K-means suffers three major shortcoming it scales poorly computationally, the num-ber of clusters K has to be supplied by the user, and the search is prone to local min problems, and a partial remedy for the third Building on prior work for algorithmic accel eration that is not based on approximation we introduce a new algorithm that efficiently searches the space of cluster locations and number of clusters to optimize the Bayesia Information Criterion (BIC) or the Akailo Information Criterion (AIC) measure. The innovations include two new ways of exploit ing cached sufficient statistics and a new very efficient test that in one K-means sweep se lects the most promising subset of classes for refinement. This gives rise to a fast, statistically founded algorithm that outputs both the number of classes and their parameters. Experiments show this technique reveals the true number of classes in the underlying dis-tribution, and that it is much faster than re-

1. Introduction

K-means (Duda & Hart, 1973; Bishop, 1995) has long been the workhorse for metric data. Its attractiveness lies in its simplicity, and in its local-minimum convergence properties. It has, however, three main shortcomings. One, it is slow and scales poorly with

lutions for these problems. Speed is greatly improved by embedding the dataset in a multirevolution kd-tree and storing sufficient statistics at its nodes. A careful analysis of the centroid locations allows for geomet-"proofs" about the Voronoi houndaries, and (un ike all of (Deng & Moore, 1995; Zhang et al., 1995; Moore, 1999)) there is absolutely no approximation anywhere in the computation. An additional geometric computation, blacklisting, maintains a list of just those centroids that need to be considered for a giver region (Pelleg & Moore, 2000). Blacklisting is not only xtremely fast but also scales yery well with the num ber of centroids, allowing tractable 10, 000-means algo-rithms. This fast algorithm is used as a building-block X-means: a new algorithm that quickly estimate . It goes into action after each run of K-means, making local decisions about which subset of the current centroids should split themselves in order to better fit the data. The splitting decision is done by computing

Clustering Individual Transactional Data for Masses of Users

riccardo.guidotti@isti.cnr.it

Fosca Giannotti ISTI-CNR, Pisa, Italy

ABSTRACT

Mining a large number of datasets recording human activities for making sense of individual data is the key enabler of a new way of personalized knowledge-based services. In this paper we focus on the problem of clustering individual transactional data for large mass of users. Transactional data is a very pervasive kind of information that is collected by several services, often involving huge pools of users. We propose txmeans, a parameter-free clutering algorithm able to efficiently partitioning transactional data in a completely automatic way. Txmeans is designed for the case where clustering must be applied on a massive number of different datasets, for instance when a large set of users need to be analyze individually and each of them has generated a long history of trans actions. A deep experimentation on both real and synthetic dataset shows the practical effectiveness of txmeans for the mass clustering of different personal datasets, and suggests that txmeans outpe forms existing methods in terms of quality and efficiency. Finally,

1 INTRODUCTION

The most disruptive effect of our always-connected society is data the digital breadcrumbs left behind us as a side effect of our everyday usage of digital technologies. Thanks to these data, human activities are becoming observable, measurable, quantifiable and, predictable At individual level, each person generates more than 5Gb of data per year. An avalanche of information that, for the most part, consists of transactions (or baskets), i.e., a special kind of categorical data a shopping cart, the web pages visited in a browsing session, the history. Such kind of data may be key enablers of a new waye of knowledge-based services, and of new scientific discoveries

Several application contexts involve the analysis of a large nun ber of datasets, each one characterized by different properties. For instance, this is the case of individual transactional data - retail sales, web sessions, credit card transactions, etc. - where each user produces historical data that need to be analyzed separately

Permission in mode digital set tast copies of all report of the work for procession for poster of the procession of the

ABSTRACT

This paper studies the problem of categorical data clustering, especially for transactional data characterized by high dimensionality and large volume. Starting from a heuristic method of increasing the height-to-width ratio of the cluster histogram, w develop a novel algorithm - CLOPE, which is very fast and scalable, while being quite effective. We demonstrate the performance of our algorithm on two real world datasets, and

1. INTRODUCTION

Clustering is an important data mining technique that groups together similar data records [12, 14, 4, 1]. Recently, more attention has been put on clustering categorical data [10, 8, 6, 5, 7, 13], where records are made up of non-numerical attributes ctional data, like market basket data and web usage data can be thought of a special type of categorical data having boolean value, with all the possible items as attributes. Fast and accurate

The Largeltem [13] algorithm groups large categorical da Inc. Largestem [15] agoritum group's large caegorica classiones by iterative optimization of a global criterion function. The criterion function is based on the notion of large item that is the tien in a cluster having occurrence rates larger than a user-defined parameter minimum support. Computing the global criterion function is much faster than those food criterion functions defined the state than those food retirerion functions defined the contraction is much faster than those food retirerion functions defined the contraction of the co on top of pair-wise similarities. This global approach make LargeItem very suitable for clustering large categorical datab

In this paper, we propose a novel global criterion function that by increasing the height-to-width ratio of the cluster histogram.

Moreover, we generalize the idea by introducing a parameter to control the tightness of the cluster. Different number of clusters can be obtained by varying this parameter. Experiments show that our algorithm runs much faster than Largeltem, with clustering y quite close to that of the ROCK along

To gain some basic idea behind our algorithm, let's take a small market basket database with 5 transactions {(apple, banana) (apple, banana, cake), (apple, cake, dish), (dish, egg), (dish, egg, fish)). For simplicity, transaction (apple, banana) is abbreviated to ab, etc. For this small database, we want to compare the following two clustering (1) {{ab, abc, acd}, {de, def}} and (2) {{ab, abc} (acd. de. def)). For each cluster, we count the occur distinct item, and then obtain the height (H) and width (W) of the cluster. For example, cluster {ab, abc, acd} has the occurrences o a:3, b:2, c:2, and d:1, with H=2.0 and W=4. Figure 1 shows these results geometrically as histograms, with items sorted in revers order of their occurrences, only for the sake of easier visus

Figure 1. Histograms of the two clusterings

We judge the qualities of these two clusterings geometrically, by analyzing the heights and widths of the clusters. Leaving out the two identical histograms for cluster (de, def) and cluster (ab, abc) the other two histograms are of different quality. The histogram for cluster (ab, abc, acd) has only 4 distinct items for 8 blocks

Exercises Transactional Clustering

- Suppose we have four verses contains some subjects, as follows:
- P1={ judgment, faith, prayer, fair}
- P2={ fasting, faith, prayer}
- P3={ fair, fasting, faith}
- P4={ fasting, prayer, pilgrimage}
- the similarity threshold = 0.3, and number of required cluster is 2.

Using Jaccard coefficient as a similarity measure, we obtain the following similarity table

	P1	P2	P3	P4
P1	1	0.4	0.4	0.17
P2		1	0.5	0.5
P3	8		1	0.2
P4				1

- Since we have a similarity threshold equal to 0.3, then we derive the adjacency table: ->
- By multiplying the adjacency table with itself, we derive the following table which shows the number of links (or common neighbors): ->

	P1	P2	P3	P4
P1	1	0.4	0.4	0.17
P2		1	0.5	0.5
P3	3 1	9 2	1	0.2
P4				1

	P1	P2	P3	P4
P1	1	1	1	0
P2		1	1	1
P3		3 A	1	0
P4				1

	P1	P2	P3	P4
P1	-	3	3	1
P2		67/6	3	2
P3			122	1
P4				-

 we compute the goodness measure for all adjacent points, assuming that

•
$$f(\theta) = 1 - \theta / 1 + \theta = 1 - 0.3 / 1 + 0.3 = 0.54$$

we obtain the following table

• we have an equal goodness measure for merging ((P1,P2), (P2,P3), (P3,P1))

$\alpha(P,P) =$	lini	$k[P_i, P_j]$	
$g(I_i,I_j)$ –	$\frac{(n+m)^{1+2f(\theta)}}{(n+m)^{1+2f(\theta)}}$	$-n^{1+2f(\theta)}$	$-m^{1+2f(\theta)}$

Pair	Goodness measure
P1,P2	1.35
P1,P3	1.35
P1,P4	0.45
P2,P3	1.35
P2,P4	0.90
P3,P4	0.45

• Now, we start the hierarchical algorithm by merging, say P1 and P2.

• A new cluster (let's call it C(P1,P2)) is formed.

• It should be noted that for some other hierarchical clustering techniques, we will not start the clustering process by merging P1 and P2, since Sim(P1,P2) = 0.4,which is not the highest. But, ROCK uses the number of links as the similarity measure rather than distance.

 Now, after merging P1 and P2, we have only three clusters. The following table shows the number of common neighbors for these clusters: >

 Then we can obtain the following goodness measures for all adjacent clusters:

	C(P1,P2)	P3	P4
C(P1,P2)		3+3	2+1
P3		6576	1
P4		9 8	199

Pair	Goodness measure
C(P1,P2),P3	1.31
C(P1,P2),P4	0.66
P3,P4	0.45

• Since the number of required clusters is 2, then we finish the clustering algorithm by merging C(P1,P2) and P3, obtaining a new cluster C(P1,P2,P3) which contains {P1,P2,P3} leaving P4 alone in a separate cluster.

 Given the following similarity matrix find the clustering result knowing that the similarity threshold = 0.4, and number of required cluster is 2.

	р1	p2	р3	р4	р5
p1	1	0.7	0.2	0.5	0.5
p2		1	0.6	0.8	0.1

Clope Exercise 1

Split1:

- 4 transactions: abc, abc, ab, a
 - a: 4, b:3, c: 2 -> sol: S=9; W=3; H=9/3=3; H/W=1
- 3 transactions: def, de, de
 - d: 3, e:3, f: 1 -> sol: S=7; W=3; H=7/3=2.33; H/W=0.77

Split2:

- 2 transactions: abcd, ab
 - a: 2, b:2, c: 1, d:1 -> sol: S=6; W=4; H=6/4=1.5; H/W=0.37
- 2 transactions: ec, ec
 - e:2, c: 2 -> sol: S=4; W=2; H=4/2=2; H/W=1

Split1 is the best clustering considering r=2

Profit(Split1) =
$$(9/3^2 * 4 + 7/3^2 * 3) / 7 = 0.90$$

Profit(Split2) = $(6/4^2 * 2 + 4/2^2 * 2) / 4 = 0.16$

$$Profit_{r}(\mathbf{C}) = \frac{\sum_{i=1}^{k} \frac{S(C_{i})}{W(C_{i})^{r}} \times |C_{i}|}{\sum_{i=1}^{k} |C_{i}|}$$
